Homework 0

Harvard University

Fall 2017

Instructors: Pavlos Protopapas, Kevin Rader, Rahul Dave, Margo Levine

This is a homework which you must turn in.

This homework has the following intentions:

- 1. To get you familiar with the jupyter/python environment (whether you are using your own install or jupyterhub)
- 2. You should easily understand these questions and what is being asked. If you struggle, this may not be the right class for you.
- 3. You should be able to understand the intent (if not the exact syntax) of the code and be able to look up google and provide code that is asked of you. If you cannot, this may not be the right class for you.

```
In [1]: # The line %... is a jupyter "magic" command, and is not part of the Python langual
# In this case we're just telling the plotting library to draw things on
# the notebook, instead of on a separate window.
%matplotlib inline
# See the "import ... as ..." contructs below? They're just aliasing the package
# That way we can call methods like plt.plot() instead of matplotlib.pyplot.plot()
import numpy as np
import matplotlib.pyplot as plt
```

Simulation of a coin throw

We dont have a coin right now. So let us **simulate** the process of throwing one on a computer. To do this we will use a form of the **random number generator** built into numpy. In particular, we will use the function np.random.choice, which will pick items with uniform probability from a list (thus if the list is of size 6, it will pick one of the six list items each time, with a probability 1/6).

This next line gives you a True when the array element is a 'H' and False otherwise.

```
In [3]: throws == 'H'

Out[3]: array([ True, False, False, True, True, False, False, False, False, False, False, False, False, False, True, False, True, False, True, False, True, False, True, False, False, True
```

If you do a np.sum on the array of Trues and Falses, python will coerce the True to 1 and False to 0. Thus a sum will give you the number of heads

Notice that you do not necessarily get 20 heads.

Now say that we run the entire process again, a second **replication** to obtain a second sample. Then we ask the same question: what is the fraction of heads we get this time? Lets call the odds of heads in sample 2, then, p_2 :

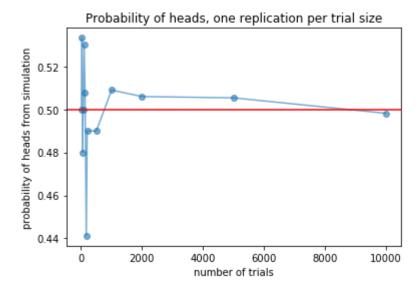

Q1. Show what happens as we choose a larger and larger set of trials

Do one replication for each size in the trials array below. Store the resultant probabilities in an array probabilities. Write a few lines on what you observe.

```
In [7]: trials = [10, 30, 50, 70, 100, 130, 170, 200, 500, 1000, 2000, 5000, 10000]
```

```
In [8]: # your code here
probabilities = []
for i in trials:
    throws = throw_a_coin(i)
    probabilities.append(np.sum(throws == 'H')/i)
```

```
In [9]: plt.plot(trials, probabilities, 'o-', alpha=0.6);
   plt.axhline(0.5, 0, 1, color='r');
   plt.xlabel('number of trials');
   plt.ylabel('probability of heads from simulation');
   plt.title('Probability of heads, one replication per trial size');
```

What did you observe?

The more times we flip, the probability is closer to 0.5.

Multiple replications of the coin flips

Lets redo the experiment with coin flips that we started above. We'll establish some terminology at first. As notation we shall call the size of the trial of coin flips n. We'll call the result of each coin flip an observation, and a single replication (which is what we did above) a sample of observations. We will do M replications (or M "samples"), for which the variable in the function below is number of samples now, for each sample size n (sample size).

Q2. Write a function to make M replications of N throws

Your job is to write a function make_throws which takes as arguments the number_of_samples (M) and the sample_size (n), and returns a list of probabilities of size M, with each probability coming from a different replication of size n. In each replication we do n coin tosses. We have provided a "spec" of the function below.

```
In [10]:
         Function
         _____
         make throws
         Generate a array of probabilities, each representing
         the probability of finding heads in a sample of fair coins
         Parameters
         number of samples : int
             The number of samples or replications
         sample_size: int
             The size of each sample (we assume each sample has the same size)
         Returns
         -----
         sample_probs : array
             Array of probabilities of H, one from each sample or replication
         Example
         >>> make_throws(number_of_samples = 3, sample_size = 20)
         [0.40000000000000000, 0.5, 0.5999999999999999]
         # your code here
         def make throws(M,n):
             probabilities = []
             for i in range(0,M):
                 throws = throw_a_coin(n)
                 probabilities.append(np.sum(throws == 'H')/n)
             return(probabilities)
```

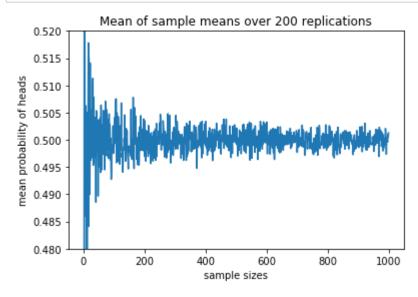

We show the mean over the observations, or sample mean, for a sample size of 10, with 20 replications. There are thus 20 means.

```
In [11]: make throws(20, 10)
Out[11]: [0.5,
      0.5999999999999998,
      0.5,
      0.6999999999999996,
      0.800000000000000004,
      0.800000000000000004,
      0.69999999999999996,
      0.2000000000000000001,
      0.5,
      0.5,
      0.59999999999999998,
      0.5999999999999998,
      0.6999999999999961
```

Q3. What happens to the mean and standard deviation of the sample means as you increase the sample size

Using the sample sizes from the sample_sizes array below, compute a set of sample_means for each sample size, and for 200 replications. Calculate the mean and standard deviation for each sample size. Store this in arrays mean_of_sample_means and std_dev_of_sample_means. The standard deviation of the sampling means is called the "standard error". Explain what you see about this "mean of sampling means".

```
In [15]: plt.plot(sample_sizes, mean_of_sample_means);
   plt.ylim([0.480,0.520]);
   plt.xlabel("sample sizes")
   plt.ylabel("mean probability of heads")
   plt.title("Mean of sample means over 200 replications");
```

Explain what you see about this "mean of sampling means".

The mean of sampling means converges to 0.5 when the sample size increase.

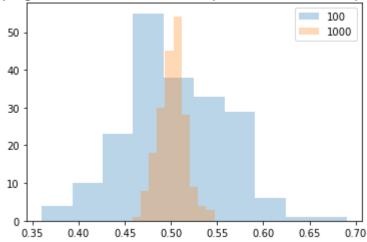

Q4. What distribution do the sampling means follow?

Store in variables sampling_means_at_size_100 and sampling_means_at_size_1000 the set of sampling means at sample sizes of 100 and 1000 respectively, still with 200 replications. We will plot in a histogram below these distributions. What type of distributions are these, roughly? How do these distributions vary with sample size?

```
In [16]: # your code here
sampling_means_at_size_100 = make_throws(200,100)
sampling_means_at_size_1000 = make_throws(200,1000)
```

In [17]: plt.hist(sampling_means_at_size_100, alpha=0.3, label="100", bins=10)
 plt.hist(sampling_means_at_size_1000, alpha=0.3, label="1000", bins=10)
 plt.legend();
 plt.title("Sampling distributions at different sample sizes and for 200 replications)

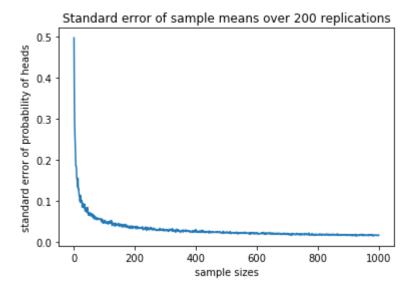

What type of distributions are these, roughly? How do these distributions vary with sample size?

It looks like a bell shape so I would say it follows a normal distribution roughly. Also there is difference between two sample size, the range of sample size 1000 is much smaller than that of sample size 100.

Q5. How does the standard error of the sample mean vary with sample size? Create a plot to illustrate how it varies over various sample sizes.

Hint: you might want to take logarithms for one of your axes

```
In [18]: # your code here
    plt.plot(sample_sizes, std_dev_of_sample_means);
    plt.xlabel("sample sizes")
    plt.ylabel("standard error of probability of heads")
    plt.title("Standard error of sample means over 200 replications");
```

How does the standard error of the sample mean vary with sample size?

As shown above, the standard error for sample size 1000 is much smaller than that for sample size 100, which means throw 1000 times, the probability will more likely fall around 0.5.
